## Abstract

We present simulations with the Chemical Lagrangian Model of the Stratosphere (CLaMS) for the Arctic winter 2002/2003. We integrated a Lagrangian denitrification scheme into the three-dimensional version of CLaMS that calculates the growth and sedimentation of nitric acid trihydrate (NAT) particles along individual particle trajectories. From those, we derive the  $\text{HNO}_3$  downward flux resulting from different particle nucleation assumptions. The simulation results show a clear vertical redistribution of total inorganic nitrogen ( $\text{NO}_y$ ), with a maximum vortex average permanent  $\text{NO}_y$  removal of over 5 ppb in late December between 500 and 550 K and a corresponding increase of  $\text{NO}_y$  of over 2 ppb below about 450 K. The simulated vertical redistribution of  $\text{NO}_y$  is compared with balloon observations by MkIV and in-situ observations from the high altitude aircraft Geophysica. Assuming a globally uniform NAT particle nucleation rate of  $3.4 \cdot 10^{-6} \text{ cm}^{-3} \text{ h}^{-1}$  in the model, the observed denitrification is well reproduced.

In the investigated winter 2002/2003, the denitrification has only moderate impact ( $\leq 10\%$ ) on the simulated vortex average ozone loss of about 1.1 ppm near the 460 K level. At higher altitudes, above 600 K potential temperature, the simulations show significant ozone depletion through  $\text{NO}_x$ -catalytic cycles due to the unusual early exposure of vortex air to sunlight.

## 1 Introduction

During the Arctic winter 2002/2003, an extensive coordinated US-European measurement campaign (SOLVE II/VINTERSOL) was carried out to investigate a variety of open questions in polar stratospheric research. Within this campaign in-situ and remote measurements from balloons, high and low flying aircraft, satellite and ground stations were collected. Most measurements were performed from Kiruna, Sweden ( $68^\circ \text{ N}$ ).

The winter 2002/2003 was characterized by extremely low temperatures in early

8070

winter (Naujokat and Grunow, 2003; Tilmes et al., 2003) that are necessary for polar stratospheric cloud (PSC) formation. Around 18 November, the temperatures fell below the threshold temperature  $T_{\text{NAT}}$  below which NAT (Nitric Acid Trihydrate) particles can exist (Hanson and Mauersberger, 1988). In December there were record-large areas with temperatures below  $T_{\text{NAT}}$ . During this time PSCs were observed both from ground based LIDAR and from satellite (Spang et al., 2004). In mid-January, a major warming led to the rise of temperatures above  $T_{\text{NAT}}$  so that PSCs disappeared. In early February the vortex stabilized again and low temperatures necessary for PSC formation were present again for a few days. Finally the vortex broke down in late April.

In this study, we focus on the simulation of denitrification throughout the winter. The importance of denitrification for polar stratospheric chemistry has been known for a long time (Fahey et al., 1990; Waibel et al., 1999). However, only in the last years the processes involved in denitrification have become clearer. In-situ observations of PSCs in the Arctic winter 1999/2000 (Fahey et al., 2001) have led to the discovery of large  $\text{HNO}_3$  containing PSC particles up to  $20\text{ }\mu\text{m}$  diameter with low number density of about  $10^{-4}\text{ cm}^{-3}$ . Due to this low number density, those particles can grow to large sizes within a few days, sediment and transport significant amounts of  $\text{HNO}_3$  downwards, consequently leading to denitrification (Carslaw et al., 2002).

In addition to the mode with low particle number density, smaller NAT particles at higher number densities of about  $10^{-3}\text{ cm}^{-3}$  have frequently been observed in the Arctic stratosphere (Deshler et al., 2003; Larsen et al., 2004; Fahey et al., 2001). Because the settling velocity of a  $3\text{ }\mu\text{m}$  diameter NAT particle is about 90 m per day on the 500 K level, the smaller particles do not sediment significantly. Instead, the growth of other NAT particles is reduced in the presence of such higher particle number densities because those particles reduce the available  $\text{HNO}_3$  in the gas phase due to uptake into the particles until equilibrium between particles and gas phase is reached. At particle number densities above  $10^{-3}\text{ cm}^{-3}$ , the equilibrium is reached within less than one day (B. Luo, personal communication, 2004). The vertical redistribution of  $\text{HNO}_3$  due to the sedimentation of the large NAT particles has an important impact on stratospheric

8071

chemistry. Firstly, the reactive surface and volume of the solid and liquid PSCs and indeed the threshold temperature for PSC existence depend on the available  $\text{HNO}_3$  in the gas phase. Secondly, a loss of  $\text{HNO}_3$  due to denitrification implies a slower increase of  $\text{NO}_x$  ( $=\text{NO}+\text{NO}_2$ ) at a later time as  $\text{HNO}_3$  is the major reservoir of  $\text{NO}_x$ . In the Arctic, the reaction of  $\text{NO}_2$  with  $\text{ClO}$  is mainly responsible for the chlorine deactivation at the end of the PSC period. Thus, the vertical redistribution of  $\text{HNO}_3$  influences both chlorine activation and deactivation. Model simulations that aim at reproducing ozone realistically must therefore include a realistic denitrification scheme. The nucleation process of NAT particles at low number densities has not yet been identified. Larger number densities of NAT particles could nucleate on ice in lee-wave events (Luo et al., 2003; Voigt et al., 2003; Carslaw et al., 2002). Recent observations (Voigt et al., in preparation, 2004<sup>1</sup>; Larsen et al., 2004) show that NAT particles also form at short timescales of about one day at temperatures above the ice frost-point. Tabazadeh et al. (2002) suggested a surface nucleation mechanism, but the nucleation rate must be more than an order of magnitude lower to explain the particle observations (Larsen et al., 2004). Studies for the winter 1999/2000 use a globally uniform nucleation rate and achieve realistic denitrification (Carslaw et al., 2002; Mann et al., 2002, 2003). The NAT nucleation rates derived from observations in the winter 2002/2003 (Larsen et al., 2004, Voigt et al., in preparation, 2004<sup>1</sup>) are higher compared to the uniform nucleation rate used by Carslaw et al. (2002) in their study of denitrification in the winter 1999/2000. Another approach to explain the large NAT particle mode employs a localized nucleation on ice particles at the bottom of a so-called mother cloud (Fueglistaler et al., 2002). However, since observations show that NAT particles can nucleate without the mother cloud mechanism (Voigt et al., in preparation, 2004<sup>1</sup>), we follow here the first assumption.

<sup>1</sup>Voigt, C., Schlager, H., Luo, B., Dörnbrack, A., Roiger, A., Stock, P., Curtius, J., Vössing, H., Borrmann, S., Konopka, P., Schiller, C., Shur, G., and Peter, T.: Detection of solid Polar Stratospheric Cloud (PSC) particles at threshold formation conditions, Atmos. Chem. Phys. Discuss., in preparation, 2004.

8072

The remaining uncertainties especially with respect to the nucleation process cannot be resolved here. The aim of this study is to find combinations of parameters using the available knowledge of NAT nucleation that allow to simulate the observed denitrification.

## 5 2 Model description

Current chemistry transport model (CTM) simulations taking into account vertical  $\text{NO}_y$  redistribution by sedimentation of large NAT particles use a combination of a Lagrangian particle model with an Eulerian CTM (Carslaw et al., 2002; Mann et al., 2003). Here, we present simulations in which both the NAT particles and the chemistry are simulated in a Lagrangian way.

The Chemical Lagrangian Model of the Stratosphere (CLaMS) was initially developed as a two-dimensional Lagrangian chemical transport model on isentropic surfaces (McKenna et al., 2002a,b). Recently, it was further developed as a full three-dimensional model (Konopka et al., 2004a). In an earlier version of the model, denitrification was parameterized in a way that only the loss of  $\text{HNO}_3$  is described with a rate depending on the assumed size of the PSC particles (Groß et al., 2002). For this study, we use a more realistic approach that takes into account the  $\text{HNO}_3$  flux due to sedimenting large PSC particles and also considers the  $\text{HNO}_3$  increase due to particle evaporation.

The calculation of growth and evaporation of large NAT particles is carried out following the procedure described in detail by Carslaw et al. (2002). The growth of each particle leads to a change of its sedimentation velocity, which is computed with a time-step of 30 min. All particles (hereafter called particle boxes, to emphasize the technical character of the term and to avoid misinterpretation and confusion) are advected horizontally on isentropic levels using the background wind fields. The vertical motion is calculated using the sedimentation velocity only. The particle boxes are advected until the particles have evaporated completely. New particle boxes are nucleated every

8073

24 h within 22 isentropic layers between 400 and 700 K north of  $50^\circ$  N at locations with  $T < T_{\text{NAT}}$  with a mean distance of 100 km, the density of particle boxes being a factor of about 4 higher than the density of the CLaMS air parcels for which the chemistry is calculated. This was done to assure that in areas where particle boxes occur, all

CLaMS air parcels have the chance to interact with at least one particle box.

Each particle box represents a much higher number of real atmospheric particles to keep the number of simulated particle boxes computationally manageable. Similar to Carslaw et al. (2002), a scaling factor in form of a number density is applied during the interaction between the particle boxes and the background chemistry. An effective nucleation rate can be calculated from the product of the number density of atmospheric particles in the newly added particle boxes and the ratio of the particle boxes and the air parcels, divided by the CLaMS time step (24 h).

The interaction between the particle boxes and the background chemistry is managed by first determining the three nearest neighboring air parcels within the layers above and below the current position of every particle box, thus creating a polyhedron containing the particle box. Nitric acid and water vapor being taken up or released during growth or evaporation, respectively, are then taken from or added to these six nearest air parcels using a distance depending weight. The impact of the interaction between particle boxes and air parcels is then determined by assigning a particle number density (the above mentioned scaling factor) to each particle box to compute the exchange of nitric acid and water vapor.

In this context it should be noted, that the density of the air parcels within each isentropic layer are not conserved during the simulation due to the properties of the mixing algorithm. This was also taken into account when calculating the mass exchange between CLaMS air parcels and particle boxes by applying an appropriate correction factor.

In sensitivity simulations, we changed the nucleation rate in the model to investigate its impact on the resulting denitrification. In the standard case, we use a constant effective nucleation rate of  $3.4 \cdot 10^{-6} \text{ cm}^{-3} \text{ h}^{-1}$  at all locations where  $T < T_{\text{NAT}}$ , comparable

8074

to the nucleation rate derived by Carslaw et al. (2002) for the winter 1999/2000, because this results in the best comparison with the observations (see below). This is about a factor of 2.3 lower than the rate reported by Voigt et al. (in preparation, 2004<sup>1</sup>) and a factor of 7.3 lower than the rate suggested by Larsen et al. (2004). Therefore, we performed sensitivity studies by changing the NAT nucleation rate to investigate its impact on denitrification.

The mode with high particle number density was not generated by the sedimentation scheme. To achieve this mode we used the microphysics module already implemented in CLaMS (Carslaw et al., 1995; McKenna et al., 2002b), in which a particle mode with given number density (here:  $0.003 \text{ cm}^{-3}$ ) can nucleate upon cooling from liquid aerosol at a certain supersaturation with respect to NAT or from sulfuric acid tetrahydrate (SAT). This critical supersaturation of  $\text{HNO}_3$  over NAT was varied from 10 to 100 and was set to 30 in the reference simulation corresponding to a temperature about 5 K below  $T_{\text{NAT}}$ . NAT formation from SAT is possible in this scheme but is not allowed in the reference simulation. Sedimentation of this mode is not considered. Therefore there are 3 possibilities to change the denitrification parameterization: A change of the rate of nucleation for the mode with low particle density, a change of the critical supersaturation to form the mode with high particle density, or a change whether or not NAT particles can form on SAT upon cooling. The SAT particles in the last case originate from previously evaporated NAT particles.

In the current simulation we use a horizontal resolution of 150 km in the area north of  $40^\circ \text{ N}$  and 400 km between the equator and  $40^\circ \text{ N}$  for the air parcels. The vertical model domain is between 350 and 900 K potential temperature divided into 21 levels. A simulation with higher resolution (100 km horizontal, 30 levels) was also performed to investigate some model resolution issues. Due to the high numerical costs, this simulation was not repeated for sensitivity studies.

8075

### 3 Initialization and boundary conditions

The presented CLaMS simulation was started for 17 November 2002 to ensure that it starts before the onset of PSC formation that is also the begin of denitrification. The chemical composition of the air parcels in the model domain was derived differently for the individual chemical species depending on the available data.

The initialization of  $\text{O}_3$  was based on the MIPAS-ENVISAT data from 16 and 17 November 2002. Here, we used the near-real-time data version of the MIPAS data provided by the European Space Agency (ESA). Data profiles for which the retrieval is potentially disturbed due to PSCs are excluded from the data set using the cloud index defined by Spang et al. (2004). From the observation locations and times trajectories on 19 isentropic levels between 350 and 2000 K were started to determine the locations of the observed air masses at the synoptic time 17 November 12 UT. These data then were gridded onto a regular  $2^\circ \times 6^\circ$  latitude-longitude grid on each level. Points within 440 km distance of a grid point contributed to it with different weights taking into account its distance and its given relative accuracy.  $\text{CH}_4$  was initialized using HALOE satellite and MkIV balloon data. Since HALOE observations (Russell et al., 1993) are available much less frequently than MIPAS data, a different method and a longer time interval was used. The HALOE  $\text{CH}_4$  observations of November and December 2002 were averaged into equivalent latitude bins on the different isentropic levels. Since HALOE did barely sample the vortex during this time the data were combined with vortex  $\text{CH}_4$  observations on 16 December 2002 obtained by MkIV (Toon et al., 1999). Correlations of  $\text{CH}_4$  with other compounds ( $\text{N}_2\text{O}$ ,  $\text{Cl}_y$ ,  $\text{Br}_y$ ) were used as in Grooß et al. (2002), with the exception that  $\text{Br}_y$  was increased by 10% to maximum mixing ratios of about 20 ppt. Total reactive nitrogen ( $\text{NO}_y$ ) was initialized using the correlation with  $\text{N}_2\text{O}$  given by Popp et al. (2001). For air parcels with  $\text{N}_2\text{O}$  mixing ratios between 1 and 33 ppb the correlation was extended here on the basis of the same data (MkIV balloon profile in December 1999) using the following correlation:

$$[\text{NO}_y] = 11.7 + 4.49 \cdot \ln[\text{N}_2\text{O}] - 0.948 \cdot (\ln[\text{N}_2\text{O}])^2, \quad (1)$$

8076

where  $\text{NO}_y$  and  $\text{N}_2\text{O}$  mixing ratios are given in ppb.

The sulfate background aerosol in the model is given as  $\text{H}_2\text{SO}_4$  equivalent gas phase mixing ratio. Its altitude dependence (given in ppb) was derived from a detailed study (Bausch et al., manuscript in preparation) to be

$$[\text{H}_2\text{SO}_4] = 1.21 \cdot 10^{-8} \theta^3 - 3.67 \cdot 10^{-5} \theta^2 + 2.96 \cdot 10^{-2} \theta - 7.97, \quad (2)$$

for the potential temperature range  $450 \text{ K} \leq \theta \leq 900 \text{ K}$ . At the lower and upper boundary of the model domain (350 and 900 K), also the chemical composition of the air parcels was prescribed derived in a similar way from the satellite data.

Similar as the initialization, the boundary conditions at upper and lower boundary of the model domain were determined. At the upper boundary (900 K), ENVISAT-MIPAS data for  $\text{O}_3$  and  $\text{CH}_4$  were averaged over equivalent latitude bins for the simulation time every half month within 5 days. From that data, the same correlations as above were used to determine  $\text{N}_2\text{O}$ ,  $\text{Cl}_y$ ,  $\text{Br}_y$ , and  $\text{NO}_y$ . Species not mentioned and the partitioning within the families were taken from the Mainz 2-D photochemical model (Grooß, 1996). Also the lower boundary composition at 350 K was taken from that model.

The ozone mixing ratio needed for the radiative transfer code (Becker et al., 2000) that determines the photolysis rates has been taken from a climatology based on HALOE measurements as function of latitude, pressure and month (Russell et al., 1993; Grooß and Russell, in preparation, 2004<sup>2</sup>).

## 4 Denitrification

Figure 1 shows the simulated  $\text{NO}_y$  change due to the sedimentation of the large NAT particles averaged over equivalent latitude range  $65\text{--}90^\circ \text{ N}$  for the reference simulation. The unperturbed  $\text{NO}_y^*$  was simulated by a passive tracer that was initialized identically

<sup>2</sup>Grooß, J.-U. and Russell, J. M.: Technical Note: A climatology based on HALOE data, Atmos. Chem. Phys. Discuss., in preparation, 2004.

8077

as  $\text{NO}_y$  and that was then advected and mixed without chemistry and denitrification. The maximum denitrification of over 5 ppb is reached in early January. After that, no significant additional denitrification was simulated and the denitrified air masses were only advected further. Also clearly visible is the re-nitrification at lower levels caused by the evaporation of the NAT particles. The diabatic descent within the polar vortex causes the downward motion of the denitrification peak. The mixing ratio increase at the re-nitrification altitudes is lower than the mixing ratio decrease at denitrification altitudes, because the total mass of sedimented  $\text{HNO}_3$  should be conserved and the pressure increases with decreasing altitude. Visible is also the very small chemical production of  $\text{NO}_y$  through the reaction of  $\text{N}_2\text{O}$  with  $\text{O}(^1\text{D})$  in early February above 600 K.

Figure 2 shows examples for simulated  $\text{NO}_y$  change on 19 January for the 425 K and 450 K levels. Note that the simulated  $\text{NO}_y$  redistribution is very inhomogeneous in space at that time. This is due to the temperature threshold of the process. At locations with temperatures just above  $T_{\text{NAT}}$ , all NAT particles evaporate relatively fast, which leads to strong re-nitrification, while possibly particles at close by locations with slightly lower temperatures can sediment further down.

In the following we show comparisons of the simulated denitrification with observations from MkIV and the Geophysica.

### 4.1 Early denitrification observed by MkIV

On 16 December 2002, the MkIV experiment on board the OMS remote balloon gondola measured  $\text{N}_2\text{O}$  and all major  $\text{NO}_y$  compounds among many other species (Toon et al., 1999). At that time, already an onset of denitrification was both observed and simulated. These data are an important constraint for the denitrification parameterization. Figures 3 and 4 show the observations of  $\text{NO}_y$  (green line) and  $\text{NO}_y^*$  derived from  $\text{N}_2\text{O}$  (green dotted line) using the correlation mentioned above. The deviation between  $\text{NO}_y$  and  $\text{NO}_y^*$  from MkIV between about 500 and 650 K is very likely caused by denitrification. The colored lines show the corresponding CLaMS  $\text{NO}_y$  mixing ratios

8078

for different parameterizations of denitrification. In Fig. 3 the nucleation rate of sedimenting the NAT particles was varied from  $1.7$  to  $8.0 \cdot 10^{-6} \text{ cm}^{-3} \text{ h}^{-1}$ . These results show clearly that an increase of the nucleation rate yields larger denitrification. For the reference simulation (marked blue in all figures unless otherwise stated) the nucleation rate of  $3.4 \cdot 10^{-6} \text{ cm}^{-3} \text{ h}^{-1}$  yields the best agreement with observed  $\text{NO}_y$ , the use of a larger nucleation rate overestimates the denitrification. Additionally, the dependence of the denitrification on the NAT nucleation rate was investigated for the whole vortex area over the winter 2002/2003 (not shown here). The maximum difference of simulated  $\text{NO}_y$  mixing ratio between simulations with the nucleation rates  $8.0 \cdot 10^{-6}$  and  $3.4 \cdot 10^{-6} \text{ cm}^{-3} \text{ h}^{-1}$  averaged over equivalent latitudes above  $65^\circ \text{ N}$  was found on 15 and 16 December (1.4 ppb at about 550 K). This indicates that the sensitivity with respect to the nucleation rate is not special for the observation location but typical for the whole vortex area. In later winter, the difference between the two simulations decreases with time, e.g. the vortex average  $\text{NO}_y$  difference on 19 January peaks at 550 K to be only 0.7 ppb. In Fig. 4, the conditions of formation of the mode with high NAT density are varied. The red line shows a simulation in which NAT formation from liquid aerosol is suppressed, the blue and the orange line shows simulations in which the mode with high NAT density is formed at supersaturation 30 and 10, respectively. All these simulations with the nucleation rate  $3.4 \cdot 10^{-6} \text{ cm}^{-3} \text{ h}^{-1}$  show almost identical denitrification at the location of the MkIV observation. This is most likely because these supersaturations are not reached in the history of the observed air masses. Alternatively, the observed denitrification could be explained by using higher nucleation rates in combination with hindering the growth of the NAT particles by the presence of a NAT mode with high particle density. This mode has been observed in December 2002 by Balloon and satellite measurements (Larsen et al., 2004; Spang et al., 2004). As shown in Fig. 4, this mode cannot be obtained in this case by varying the NAT supersaturation necessary to form NAT, but it can be reached by allowing NAT particles on SAT. The pink line shows a simulation in which the formation of NAT from SAT is allowed and the nucleation rate was doubled ( $6.8 \cdot 10^{-6} \text{ cm}^{-3} \text{ h}^{-1}$ ). Both effects approximately

8079

compensate. The SAT particles in the simulation originate from previously evaporated NAT particles that remained below the melting temperature of about 215 K. However, laboratory studies show that NAT nucleation on SAT is unlikely (Iraci et al., 1995; Koop et al., 1997). But similar results should be expected if instead of SAT other yet unknown condensation nuclei would form NAT. Although these assumptions yield a quite similar denitrification as the reference simulation for the MkIV observations in December, they yield lower  $\text{NO}_y$  redistribution in January and worse agreement with  $\text{NO}_y$  observations on the Geophysica that are shown in the next section. Therefore the assumption of NAT nucleation on SAT is not considered further.

On about 480 K potential temperature, the MkIV observations suggest re-nitrification that seems not to be represented in the simulation. To investigate this deviation, we simulated the  $\text{NO}_y$  redistribution with higher model resolution (100 km/30 levels). Figure 5 shows the simulated  $\text{NO}_y$  change on the 480 K level. Here, the air in the vortex core is denitrified. Around this denitrified area, a filament of re-nitrified air is visible very close to the location of the MkIV observation (pink circle). Also the high resolution simulation suggests no significant re-nitrification exactly at the observation location, it seems that the end of the filament was just missed. We conclude that this discrepancy between observation and model is likely a matter of model resolution or slight wind or temperature uncertainties of the meteorological analyses.

## 4.2 Comparison with geophysica observations

Between 15 January and 9 February, stratospheric in-situ measurements were obtained on 9 flights of the Geophysica aircraft within the scope of the VINTERSOL-EUPLEX campaign. Observations of chemically stable tracers can be used to validate the transport of the simulation. Figure 6 shows the comparison of HAGAR observations (Volk et al., in preparation, 2004<sup>3</sup>) and CLaMS simulation of the tracer  $\text{N}_2\text{O}$

<sup>3</sup>Volk, C. M., Werner, A., Wetter, T., Ivanova, E., Wollny, A., Ulanovsky, A., Ravegnani, F., Schlager, H., Konopka, P., and Toon, G.: Ozone loss within the 2003 Arctic vortex derived from

that can be considered as chemically inert over the winter. The left panel shows the comparison along the flight of 19 January 2003. The right panel shows a scatter plot for all obtained N<sub>2</sub>O observations between 19 January and 9 February 2003 and the corresponding CLaMS observations. There is some indication that the model over-estimates N<sub>2</sub>O for mixing ratios below about 100 ppb, but in general this comparison shows that the simulation is able to reproduce well the advection and mixing of the air masses. An increase of resolution to 100 km horizontal resolution and 30 vertical levels did slightly improve this comparison at the expense of high numerical costs. But the current resolution seems to be sufficient for the purpose of this study.

Between 15 January and 4 February, no PSC particles are simulated by the sedimentation scheme which is expected because of the major warming in January. Therefore, no additional denitrification was simulated during this time period, but the denitrified air masses were advected. We compare the simulated denitrification with observations of denitrification determined from the difference of NO<sub>y</sub> measured by the SIOUX instrument (Schlager et al., in preparation, 2004<sup>4</sup>; Voigt et al., in preparation, 2004<sup>1</sup>) and NO<sub>y</sub><sup>\*</sup> derived from the HAGAR N<sub>2</sub>O measurements shown above without having to consider HNO<sub>3</sub> in the particle phase at these high temperatures. Figure 7 shows in the top panel the altitude dependence of vertical NO<sub>y</sub> redistribution for the parts of the flight of 19 January within the polar vortex (equivalent latitude >70°). The shape of the denitrification and re-nitrification profile is reproduced well. The absolute values are slightly under-estimated for  $J=3.4\cdot10^{-6}\text{ cm}^{-3}\text{ h}^{-1}$  and agree better for  $J=8.0\cdot10^{-6}\text{ cm}^{-3}\text{ h}^{-1}$ . The larger nucleation rate produces slightly higher denitrification and renitrification and the results may agree slightly better with the observations. Both, observations and the simulation do show the turnover level from denitrification to re-nitrification at about 440 K.

<sup>4</sup>Schlager, H., Voigt, C., Volk, M., Davies, S., Carslaw, K., Konopka, P., Roiger, A., and Stock, P.: Observations of denitrification and renitrification in the 2002–2003 Arctic winter stratosphere, *Atmos. Chem. Phys. Discuss.*, in preparation, 2004.

8081

440 K at that time. The northward part of the flight on 19 January was flown around that 440 K level. At this level CLaMS underestimates the re-nitrification. This may be caused by a too coarse vertical model resolution since a small deviation in altitude corresponds to a large deviation of NO<sub>y</sub>-NO<sub>y</sub><sup>\*</sup> at this level.

The lower two panels of Fig. 7 show the comparison for all observations between 19 January and 9 February 2003 for both choices of the nucleation rate. The results are very similar and from this figure it cannot be deduced which nucleation rate  $J$  should be more likely. For the larger nucleation rate slightly higher denitrification and also re-nitrification is simulated and the results may agree slightly better with the observations.

The reason for the similar results using the different nucleation rates is a saturation effect. Since less HNO<sub>3</sub> is available in denitrified air, the threshold temperature for NAT formation is lowered and therefore additional denitrification is hindered. Therefore, the simulated vertical NO<sub>y</sub> redistribution depends significantly on the assumed particle nucleation rate most notably in early winter shortly after the onset of PSCs.

Also, the reference simulation was continued until mid-March. In March, the denitrification is still well simulated. Figure 8 shows the comparison of simulated NO<sub>y</sub>-NO<sub>y</sub><sup>\*</sup> with derived denitrification from SIOUX and HAGAR for the flights on 8 March and 12 March for equivalent latitudes above 60° N during the Envisat validation campaign.

## 5 Simulated ozone depletion

To investigate the ozone depletion in the winter 2002/2003, the simulation was continued until mid-March in order to include the second period of low stratospheric temperatures in mid-February. Here we show the results with the high horizontal resolution of 100 km. Similar as for the denitrification, the chemical ozone depletion was determined by taking the difference between model ozone and a passive ozone tracer that was initialized on 17 December identically as ozone and that is advected and mixed without chemical change. The simulated ozone depletion averaged over the vortex as defined by Nash et al. (1996) as function of time and potential temperature is shown in Fig. 9.

8082

The simulations indicate that vortex average ozone depletion reaches about 1.1 ppm in mid-March around the 460 K level. The simulated vortex average ozone column loss on 13 March between 380 K and 500 K was 46 Dobson units (21% of the partial ozone column), and between 350 K and 900 K it was 67 Dobson units (18%). To verify that the ozone depletion was simulated correctly over the winter, the simulated ozone mixing ratios were compared with observations of ozone on 14 March 2003 made by MIPAS-ENVISAT. On that day, MIPAS data did have a good coverage of the polar vortex. Figure 10 shows the one to one comparison for MIPAS observations between 350 and 500 K potential temperature and for equivalent latitudes above 60° N. The differences between simulation and observations can be explained by small-scale structures below the resolution of CLaMS and the accuracy of the MIPAS observations of about 10% (Blumenstock et al., 2003). The average difference ( $\pm 1\sigma$ ) between simulated and observed ozone mixing ratios (CLaMS–MIPAS) is  $-0.07 \pm 0.25$  ppm. The largest differences in the comparison occur at the edge and outside the vortex, for equivalent latitudes below 70° N. Figure 11 shows ozone comparisons with the FOX instrument (Schlager et al., in preparation, 2004<sup>4</sup>) on board the Geophysica aircraft made during the Envisat validation campaign between 28 February and 16 March. Here the average difference (CLaMS–FOX) is also low  $-0.06 \pm 0.18$  ppm. This indicates that all significant ozone loss processes in the vortex have been covered by the simulation.

The magnitude of the ozone depletion is comparable with estimates derived from HALOE data using the tracer correlation method (Tilmes et al., 2003), but the altitude of the maximum ozone depletion is about 25 K higher in the simulation. Goutail et al. (2004) report a slightly higher amount of ozone depletion, 23% of the total column derived from observations SAOZ UV-visible spectrometers and CTM passive ozone simulations. However, due to the different altitude range the results are not completely comparable.

To compare with the results of Feng et al. (2004), one has to take into account that they use absorption cross section of the photolysis of  $\text{Cl}_2\text{O}_2$  by Burkholder et al. (1990) extrapolated to the wavelength of 450 nm instead of those recommended by

8083

Sander et al. (2003) that were used here. Therefore sensitivity simulations (150 km resolution) were carried out with this absorption cross section which leads to more ozone depletion. In this simulation, the ozone column between 380 K and 550 K averaged for equivalent latitudes above 65° N decreased by about 2.4 Dobson units by mid January and remained about constant at that value until the end of the simulations. This corresponds to an increase of the column ozone depletion between 380 K and 550 K relative to the reference simulation of at most 13.5% on 11 January. At 12 March this corresponds to 6.0% more ozone depletion compared to the reference simulation. Feng et al. (2004) show the partial ozone column loss between 345 K and 670 K averaged for areas above 65° N equivalent latitude. The time development of the simulated ozone loss in our simulation (350 K–670 K) is comparable until mid February. In early to mid-March, CLaMS simulates less ozone depletion, e.g. 50 Dobson units on 16 March, that is about 8 Dobson units less ozone depletion than Feng et al. (2004). As shown above, only 2–3 Dobson units of the difference can be explained by the different  $\text{Cl}_2\text{O}_2$  photolysis. One possible reason for the remaining difference may be a difference in the simulated denitrification as explained below. However, in our simulation there is also no indication that the denitrification is not correctly simulated in March (compare Fig. 8). Further, the impact of denitrification on the simulated ozone depletion was investigated through an additional simulation in which the sedimentation scheme was deactivated. This was done with the lower horizontal resolution of 150 km. In general, the simulated ozone depletion is very similar to the reference simulation. The largest effect of the denitrification was found towards the end of the simulation when the deactivation of active chlorine species is hindered by the denitrification. The maximum of the ozone depletion due to denitrification averaged over the vortex as defined by Nash et al. (1996) was determined to be 100 ppb at 460 K potential temperature corresponding to 10% of the ozone depletion of the reference simulation.

Another striking feature is the simulated ozone depletion above the 600 K level. Unlike the levels below about 500 K where ozone loss is mainly caused by catalytic cycles involving chlorine and bromine compounds, no PSCs and no chlorine activation are

8084

simulated at these altitudes. The reason for the ozone depletion above 600 K are catalytic cycles involving  $\text{NO}_x$ . Especially in the winter 2002/2003, that was dynamically active, the time when vortex air was exposed to sunlight began earlier and was longer than in other winters. Therefore, also the typical summer ozone depletion started earlier. Such a behavior was also observed in the dynamically active 2002 Antarctic winter (Grooß et al., 2004).

The chemical ozone depletion inside the vortex at altitudes above 600 K was also found in the comparison of a high resolution CLaMS tracer simulation and MIPAS observations (Konopka et al., in preparation, 2004b<sup>5</sup>). A similar comparison as above with MIPAS data on 14 March 2003 between 500 K and 800 K yields a mean difference (CLaMS-MIPAS) of  $+0.30 \pm 0.45$  ppm. That means the simulation slightly underestimates the ozone depletion in that altitude range.

## 6 Conclusions

A Lagrangian module for single particle growth and advection was developed and integrated in the Chemical Lagrangian Model of the Stratosphere (CLaMS). With this model, the vertical redistribution of  $\text{NO}_y$  for the winter 2002/2003 was successfully simulated. The presented simulations demonstrate that choosing a nucleation rate of  $J = 3.4 \cdot 10^{-6} \text{ cm}^{-3} \text{ h}^{-1}$  results in the best reproduction of the observed  $\text{NO}_y$  in mid-December 2002. For that time period shortly after the onset of PSCs, the simulated denitrification is most sensitive to the nucleation rate in the absence of the mode with high particle density. It has been also shown that the presence of the mode with high particle density (Larsen et al., 2004; Spang et al., 2004) decelerates the growth of the large NAT particles. Thus, in the presence of higher NAT particle number densities, the

8085

nucleation rate has to be increased to achieve similar results. Later in the winter in mid-January to early February, the simulated denitrification does not significantly depend on the nucleation rate.

Further, the simulated ozone loss over the simulation period was determined. By mid-March the vortex averaged ozone loss around 460 K was about 1.1 ppm comparable to other ozone loss estimates. A sensitivity simulation showed that 10% of the ozone loss can be attributed to denitrification. At higher altitudes above 600 K also significant ozone loss was determined. This loss was caused by  $\text{NO}_x$ -catalyzed ozone loss cycles in vortex air masses with large exposure to sunlight.

*Acknowledgements.* The authors thank B. Luo and T. Deshler for fruitful discussions. The European Centre for Medium-Range Weather Forecasts (ECMWF) provided meteorological analyses and forecasts during campaign that were very helpful for flight planning. The European Space Agency (ESA) provided the ENVISAT-MIPAS data. We thank R. Spang for extracting the MIPAS data and providing the cloud index data. We also thank N. Thomas for her excellent programming support. This work was funded by the EU within the VINTERSOL-EUPLEX project.
